$_{\scriptscriptstyle 11}$ Abstract

9

10

12 Introduction

- Phenological models are expected to fit data trends within its biological field. Yet due to different
- 14 reasons, models developed and published from one sample may not fit the others. These reasons
- 15 may be due to data variabilities, confounding factors, inaccurate assumptions or models being
- too-specific. This project is aimed at compare and contrast published phenological models on
- 17 microbial population size data, highlighting which is a better model under what conditions.
- 18 The hypotheses are:
- published phenological models are better than polynomials in describing microbial population size;
- appropriate phenological model(s) can be identified through distinguishable shapes of
 microbial population size; and
- parameters of data under each phenological model is clustered, similar with dataset bestdescribed by the same model but different from those described by other models.

$_{25}$ Methods

- 26 Experimental microbial population growth data library were divided into individual data sub-
- sets through six filters ("Temperature (in °C)", "Microbial clade", "growth substrate materi-
- 28 als", "experimental replicate number", "population data recording unit" and "data source").
- 29 Records with data unit "OD_595" were scaled into optical density percentages (i.e. data*100)

to facilitate general analyses workflow. Independent (or explanatory) variable was "Time (hr)" and dependent (or response) variable was "population size".

Some raw data were recorded in minutes (instead of hour). This record artifact was not corrected because of two reasons: 1. shape of curves were the main concern instead of independent variable's scale; and 2. the unit was consistent within each data subset.

Six candidate models were assessed, four phenological and two polynomial equations. They were

"Verhulst (classical)"¹, "modified Gompertz"², "Baranyi"³, "Buchanan"⁴, "quadratic" and "cubic". NLLS was used only on the four phenological models and linear model-fitting was done 38 on the two polynomials. Starting values selection (for phenological models only) was described 39 below: Initial (N0) and final (K) population sizes were selected to be the minimum and maximum values of each data subset respectively. Maximum growth rate (r.max) was selected by linear 42 model through a recursive manner. For every iteration, population size data from the top 5% independent variable values were excluded from the linear model calculation. The data and 44 slope would only be recorded if it was positive, higher adjusted R² value and larger slope than 45 the recorded "best slope" value. After scanning from the maximum side, the best slope and its respective data were taken out and screened from the minimum side. Final best slope and x-intercept were regarded as the r.max and relative time lag (t.lag) of the population (in the source experiment) respectively. Time which this linear model intersected with K was regarded as the time achieving carrying capacity (t.K). Population data was then classified into three 50 groups (gx) according to the time: $g1 \le t.lag < g2 < t.K \le g3$. 5% was chosen as the scanning 51 threshold because I assumed this resolution was fine enough for achieving good starting values for NLLS fitting. Inputs for phenological modelswere listed below (popn & time were the dependent and independent variables respectively):

```
Verhulst (classical): popn = f(N0, K, r.max, time)

modified Gompertz: popn = f(N0, K, r.max, time, t.lag)

Baranyi: popn = f(N0, K, r.max, time, t.lag)

Buchanan: popn = f(N0, K, r.max, time, t.lag, gx)
```

All test starting values were than sampled from normal distribution with mean as the estimated value and standard deviation (sd) of 1. The sd value was chosen because of different reasons for each parameters. No and K were directly extracted from the raw experimental
data, which could be assumed being an accurate estimate for that data subset (hence a small
sd was logical). r.max was a guesstimated value from fitting linear models. This process could
potentially be affected by extreme values in the data and hence a large sd should be preferred.
100 trials were done as a optimal value under a trade-off between efficiency and accuracy.

64

Only AIC⁵⁻⁷ was used to select for optimal parameter values within each phenological model and best model between the six candidates for a data subset. Reasons would be listed in Discussion section. For models with more than one parameter sets as sharing the lowest AIC value, the first set of values from the random sampling trials were used for downstream analyses. AIC tolerance threshold was expanded to min(AIC)+2⁸ to incorporate more accepted models for analyses.

71

72 Statistical analysis

73 Main Assumptions

- there was no negative population growth (i.e. starting population was always lower than carrying capacity), so negative population growth data were set to zeros;
- estimated parameter estimates would always result in a global optimal status in parameter space through the non-linear least squares method (NLLS)

78 Computing tools

 79 R (ver 3.6.0) 9 was used with "minpack.lm" 10 for computing non-linear least square statistics for model comparisons.

Results

Discussion

- Model fitness to real data and simplistic mathematics were favoured by both AIC^{5-7} and $BIC^{5,11}$.
- Apart from that, BIC also takes account of sample size effect^{5,11}.
- comparisons in different fields^{12–17}

86 Conclusion

87 Code and Data Availability

88 All scripts and data used for this report were publicity available at GitHub.
